**Abstract**

**BACKGROUND:** Toxoplasmosis is a worldwide infection. Most studies on toxoplasmosis are in women in child bearing ages. We conducted an epidemiological survey on the population of the Isfahan Province to identify characteristics of the individuals associated with seropositivity.

**METHODS:** In a cross sectional study, 599 serum samples were randomly collected for seroepidemiology of Hepatitis A and E, and were also used for titration of IgG anti-Toxoplasma gondii antibody by a commercial enzyme-linked immunosorbent assay (ELISA) kit. Data were analyzed using SPSS software.\(^{15}\) Chi square and Fisher exact tests were employed to examine antibody status in different age, gender, education and residency groups.

**RESULTS:** The overall prevalence was 41.4% (248/599). There was a statistical significant association between seroprevalence with age, education, and gender (p < 0.05) but not with residency state. The peak age for acquisition of the infection in females was 20-29 and in males 20-39 years old.

**CONCLUSIONS:** Results of current study showed a moderate prevalence of toxoplasma gondii infection. However higher seroconversion rate in active social and reproductive ages, females and low educated individuals necessitate active preventive programs in these high risk groups.

**KEYWORDS:** Epidemiology, Toxoplasmosis, Isfahan, Iran, Population based study, Immunoassay.

Toxoplasmosis is a worldwide infection, which is primarily acquired through the ingestion of tissue cysts in poorly cooked meat or inadvertent intake of sporulated oocysts excreted in cat feces.\(^1\) The infection is mainly asymptomatic in immunocompetent humans, but it can arise to cervical lymphadenopathy, mononucleosis-like syndrome or chorioretinitis in up to 20%.\(^1\) Association to behavioral disorders like schizophrenia, mood disorders, personality changes and cognitive impairment has recently been affirmed.\(^2\) Consequences of primary infection in pregnant women with normal immunity include abortion, blindness, deafness, mental retardation, microcephalus, hydrocephalus and other neurological diseases in the fetus.\(^3\) In immune deficient individuals, primary or reactivated infection can result in encephalitis, pneumonia, myocarditis and disseminated infection.\(^1\) Considerable variation in seroprevalence of the infection have been reported in diverse regions and different individuals and various times and are chiefly related to factors that expose

the population to the infected cysts. Age, sex, ethnicity, sanitary conditions, geographic climate, cat or soil contact, patterns of work and behavior, and location and configuration of the community have been main determinant of these dissimilarities. There are many researches about the prevalence of anti-Toxoplasma gondii antibody among Iranian women. Seropositivity have been reported as 48-74.6 in northern areas, 33-44% in northwest, 22-37% in south, 27-54% in central parts of Iran. Nearly all of these surveys have been performed on females, mainly pregnant women, and based on laboratory, hospital or clinic samples that lack the statistical illustration of the whole population. Therefore, we performed a population based cross-sectional study to determine the prevalence of T. gondii infection in all inhabitants of the Isfahan province and identify the seroprevalence in different age, gender, residence, and educational groups. This provides valuable information about epidemiology of the infection and may be useful for implementing preventive measures in the community.

Methods

Ethical considerations
Before enrolment in the study, detailed information about epidemiological studies was given to the assigned individuals or their parents and written informed consent was obtained. According to the research design, if the assigned subjects reject the participation in the survey, next neighbor family was offered to partake in the study. The results of performed tests were posted to participants for further follow ups. The study was approved by the regional bioethics committee of the Research Department of Isfahan University of Medical Sciences.

Study area

Isfahan is a large province that covers an area of 107,027 km² in the central part of Iran. The area has a dry and moderate climate with average temperature of 5.7°C in winter to 27.2 °C in summer and annual rainfall of 122.7 mm. Total population at the time of survey was 4,165,319 inhabitants, 51.3% of them were male and 48.7% were female; 84.9% of them resided in urban area and 15.1% in rural districts.

Study population

For estimation of the seroprevalence of toxoplasma infection in Isfahan province, we tested serum samples which previously reserved in a seroepidemiological study on Hepatitis A and E in 2008. The above mentioned sera have been collected randomly by multistage cluster sampling method from the whole population of the Isfahan province. Briefly in a random pattern, twenty subjects from each of 41 (nine rural and 32 urban) clusters were randomly selected from the provincial health center census list and were distributed to six age groups of 6-9, 10-19, 20-29, 30-39, 40-49 and >50 years old. After providing written informed consent, 5-mL venous blood sample were collected and send to healthcare center in less than 3 hours and centrifuged at 3000 rpm for 15 minutes. Isolated sera were frozen by Alicot method and were stored at -70°C until assays. Additional frozen sera were reserved for further surveys. Simultaneously, a questionnaire including demographic and educational characteristics of the subjects was filled and coded by trained interviewers at the participants’ homes.

Sample size was calculated based on an estimated anti-toxoplasma seroprevalence of 40% in the province with 96% confidence level and 90% power. While 570 samples were required, 600 out of 816 previously collected serum samples were randomly selected for more accurate estimation in accordance to age distribution of the population in the year of the study.

Laboratory method

After selection of the required samples, the frozen sera were liquefied in room temperature and tested for the presence of IgG anti-T. gondii antibody using a commercial enzyme-linked immunosorbent assay (ELISA) kit (Dia-Pro,
Milan, Italy). According to the recommendation of the kit, absorbance levels below 9 was considered as negative, 9-11 assumed as equivocal and above 11 was positive. The samples with equivocal results were retested and were accordingly accepted as negative or positive. If the second test result was equivocal, the sample was excluded from the study.

**Statistical analysis**

Finally, the collected data were coded and analyzed using the Statistical Package for Social Sciences SPSS for Windows version 15 (SPSS Inc., Chicago IL.). Chi-square and Fisher exact tests were employed to examine antibody status in different age, gender, education and residency groups in the studied population. A P-value of less than 0.05 was considered significant.

**Results**

Out of 600 serums, which were selected for the study, one sample was excluded due to inadequate volume. Out of 599 samples enrolled, 248 cases were positive, 339 were negative and 12 samples had equivocal results. All samples with equivocal results became negative in repeat of the test.

The overall prevalence of toxoplasma gondii infection in studied population was 41.4% (248/599). Table 1 shows the distribution of the subjects and seroprevalence of them in various age, gender and residence groups. The distribution of age, gender and residence was similar to that of the whole population in Isfahan province in the year of the study.

There was a statistically significant association of toxoplasmosis seroprevalence with age and gender (p < 0.05), but the association was not significant with residency groups (p > 0.05).

Since the association of the seroprevalence with education could be misleading in ages of less than 20 years old, we assessed this in ages over 20 years old (Table 2). The results show that statistical significance decreases in seropositivity as the level of the education increases (p < 0.05).

The seroprevalence of T. gondii infection in different age and gender groups is showed in Figure 1. The rate of positive female subjects rose sharply between the groups aged 10-19 and 20-29 (19.0% and 56.5%, respectively), while in male subjects the seroprevalence was specifically increased slowly between ages of 10-19, 20-29 and 20-39 years (19.4%, 32.8% and 41.0%, respectively) (p < 0.05).

Figure 2 shows the T.gondii seroprevalence in different age and residence groups. It elucidates that the peak age of T. gondii acquisition in urban areas was less than rural districts (20-29 and 30-39 year old, respectively).

Discussion
This study showed a moderate infection (41.4%) with T. gondii protozoa in Isfahan Province, central area of Iran in comparison with other countries and other provinces in Islamic Republic of Iran. Most of the studies on toxoplasmosis have been conducted on subgroups at risk of transmitting infection to offspring mainly pregnant women, women in child-bearing ages or pre-marriage women. Different investigations throughout the world show a wide spectrum of seropositivity. While high prevalences about 75-85% have been reported from Latin America, central and east Europe and South-east Asia, lower prevalences near 20-30% are found in North America and northern Europe. In Iran, higher prevalences near 60-75% have been reported in the northern parts of the country. Lower seropositivity as 20-35% has been reported in the north-west, central and southern regions. These differences may be related to the climate condition, nutritional behavior and possessing cat, but enrolled subjects, assay and sampling methods and the year of the study may involve in differences between seroprevalence in different areas and same areas in different studies.

Results of the present study showed a significant increasing rate of seropositivity with age (Table 1), which is predictable, because older individuals have more chances for exposure to infectious form of parasite. The most interesting finding of current study was the difference between the peak age for gaining the infection in rural (20-29 years) and urban areas (30-39 years old) of the province (Figure2). In studies conducted in Venezuela and Croatia, peak age of acquisition of the infection was ages less than 15 years. In another study in twelve provinces in Iran, most people acquired the infection for 30 years and the seroconversion rate was slightly more in 10-19 years age group, which is compatible with our results. The difference in peak age of acquisition in various regions could be due to different climate conditions, dissimilar nutritional and behavioural patterns of life, which expose the population to the infective form of parasite in different ages. The highest acquisition of the infection in active social ages in Iran is alarming which necessitates preventive programs from toxoplasmosis in these high risk age groups.

In studies conducted in pregnant or premarriage women in Cuba, Denmark and Sweden and in northwest and north of Iran no significant statistical difference was established between rural and urban inhabitants. These are similar with our results (Table 1). However, some researchers found significant differences between children in rural and urban areas.

Although some researchers did not find significant relationship between infection and gender, our results elucidate higher rate of seropositivity in female subjects after adolescence. Different sampling method and also diverse lifestyle of women and men in different communities could explain this discrepancy.

The study revealed that the peak age of acquisition of the infection is different for men and women, specifically 20-30 years in females (3.76% in each year) and 20-40 years in males (2.2% in each year). The high rate of seroconversion in the peak of child bearing ages in females and active social ages in both genders is noteworthy.
Like other reports, education has inverse relation with seropositivity of *T. gondii* infection.\(^5,8,10,11\) Increased knowledge through higher education and its consequence on patterns of life and behaviours may lead to a decrease in *T. gondii* infection, and may have an indirect effect on environmental and cultural factors involved in *T. gondii* infection.

**Conclusion**

This study suggests a moderate prevalence of *T. gondii* infection in the province. The seroconversion was higher in the age group of 20-39 year old, in females and in low educated individuals, which necessitates active preventive programs in these high risk groups to control the burden of active and chronic infection in the community.
